Myxobolus insignis sp. n. (Myxozoa, Myxosporea, Myxobolidae), a parasite of the Amazonian teleost fish Semaprochilodus insignis (Osteichthyes, Prochilodontidae)

JC Eiras/+ , JCO Malta*, AMB Varella*, GC Pavanelli**

MATERIALS AND METHODS

Three specimens of S. insignis (total length: 22.3-24.5 cm) were net-fished from the Amazon river, at Manaus, and transported to the laboratory. The specimens were thoroughly dissected under a compound microscope and all the organs were inspected for the presence of parasites. Measurements were made from fresh spores (30 specimens), and spores were observed under Nomarski differential interference-contrast. For detecting the presence of an iodinophilous vacuole fresh spores were treated with Lugol’s iodine solution. Spores were also stained with India ink for revealing any mucous envelope (Lom & Vávra 1961).

RESULTS

Two specimens of S. insignis exhibited the gills infected by Myxobolus. The parasites formed whitish, rounded or slightly irregular plasmodia (about 0.02-0.08 mm in diameter) located intra-lamellarily within the secondary gill lamellae. Most of the plasmodia were located at the base of the lamellae, but could be present also more or less far from the base.

The spores (Figs 1-3) had a valvular wall 1.5-2 µm thick all around their body, and the valves were symmetrical and smooth. The spores were a little longer than wide, with rounded extremities, in frontal view, and oval in lateral view. They were 14.5 (14-15) µm long by 11.3 (11-12) µm wide and 7.8 (7-8) µm thick. Some spores showed the presence of a triangular thickening of the internal face of the wall near the posterior end of the polar capsules. This thickening could occur in one of the sides of the spore or in both sides. The polar capsules were large and equal in size surpassing the mid-length of the spore. They were oval with the posterior extremity rounded, and converging anteriorly with tapered ends. They were 7.6 (7-8) µm long by 4.2 (3-5) µm wide, and the polar filament formed 6 coils slightly obliquely to the axis of the polar capsule. An intercapsular appendix was present. There was no mucous envelope or distinct iodinophilous vacuole.

Key words: Myxozoa - Myxosporea - Myxobolus insignis sp. n. - Semaprochilodus insignis - Brazil
small intercapsular appendix was present. There was no mucous envelope or distinct iodinophilous vacuole.

Host: teleost fish *Semaprochilodus insignis* Jardine & Schomburgk, 1841
Locality: Amazon River, near Manaus, Brazil
Site of infection: inside secondary gill lamellae
Prevalence: two out of three fish were infected
Etymology: the specific name derives from the name of the host species.
Specimens deposition: the syntipes are deposited at the “Collection of Myxozoa from the National Institute for the Amazonian Research” (Inpa), Manaus, AM, Brazil, under the reference INPA-002, in the Section of Animal Pathology from the Department of Zoology and Anthropology from the Faculty of Sciences of Porto, Portugal, and in the Museum of Natural History from the Faculty of Sciences of Porto, Portugal.

**Taxonomic affinities**

Comparing our species with other *Myxobolus* described for the South American fishes it can be seen that they are different from all of them. The most similar, concerning the morphometric characteristics, are *M. absonus* Cellere, Cordeiro & Adriano, 2002, *M. associatus* Nemecek, 1926, *M. galaxii* Szidat, 1953, *M. paranensis* Bonetto & Pignalberi, 1965 and *M. pygocephalas* Penido, 1927. *M. absonus* despite some similarities in morphometric characters has unequally sized polar capsules. *M. associatus* has narrower spores and smaller polar capsules.

*M. galaxii* has spores that are narrower, and infect all the organs of the hosts except the gills, exactly the contrary occurring with our specimens. *M. paranensis* has smaller spores and smaller polar capsules, and *M. pygocephalas* has longer spores and longer polar capsules. Besides, the spores under examination have a very thick wall, a characteristic not reported for any of the South American *Myxobolus* species.

On the other hand, the spores from our material are ovoid with rounded extremities. This is clearly a different shape of a number of species that have the spores pyriform (*M. maculatus* Casal, Matos & Azevedo, 2002, *M. inaequus* Kent & Hoffman, 1984, *M. cunhai* Penido, 1927, *M. lutzi* Aragão, 1919, *M. paranensis*, *M. desaequalis* Azevedo, Corral & Matos, 2002, *M. braziliensis* Casal, Matos & Azevedo, 1996, *M. associatus*, *M. chondrophilas* Nemecek, 1926 and *M. inaequalis* Gurley, 1893), or the anterior end slightly pointed (*M. absonus* and *M. kudoi* Guimarães & Bergamim, 1938). The species which have a similar shape of the spores can not be identified as our species because they are quite different in spore size, in size and position of the polar capsules, in the number of coils of the polar filament, or do not have intercapsular appendix.
Our material was also compared with the characteristics of 744 species corresponding to nearly all the species described so far (Eiras et al. in press). Despite some similarities of some species, our specimens could not be identified as any of these species. *M. alievi* Gasi-magomedov (1970) described from *Rutilus rutilus caspicus*, and *M. lampa-formis* Chen & Ma (1989) infecting *Aristichthys nobilis* have dimensions similar in some aspects, but have unequally sized polar capsules and do not have an intercapsular appendix. *M. angustus* Kudo (1934) from the host *Cloila vigilax* has spores with the same length, but they are not so wide (7-8 µm), the polar capsules are larger and thinner (8-9.5 and 2.5-3.3 µm, respectively), and do not have intercapsular appendix. *M. baueri* Chernova, 1970, infecting *Tinca tinca*, has similar spore dimensions, but the polar capsules are distinctly smaller (5.3-6 by 2.7-3.3 µm). *M. bullulatus* Grinham & Cone, 1990, infecting *Catostomus commersonii* and *M. enoblei* Lom & Cone (1996) parasitizing *Ictiobus bubalus* has spores not so wide (10.5-11.5 µm), and longer and larger polar capsules (7.9-8.5 µm and 4.5-5.5 µm, respectively). Finally, *M. spalli* Landsgerg & Lom, 1991, has spores of the same length, but much more thin, smaller polar capsules, and do not have intercapsular appendix. Furthermore, none of the above mentioned species has a spore wall as thick as observed in our specimens.

It is concluded that the present material represents a species not yet described, and the name *Myxobolus insignis* sp. n. is proposed.
